TITLE OF THE INVENTIONMETHOD AND SYSTEM OF LASER PROCESSING/RELATED APPLICATIONS

5 This application is a continuation-in-part of Serial No. 07/891,907 filed June 1, 1992, which was a continuation of Serial No. 07/626,419 filed December 14, 1990, now abandoned, which was a continuation of Serial No. 07/288,186 filed December 22, 1988, which was a continuation-in-part of Serial No. 97,190 filed September 16, 1987 (now U.S. Patent No. 4,861,964).

10 BACKGROUND OF THE INVENTION

The present invention relates to a method of producing thin film patterns on a glass substrate.

15 Photolithography is a well-known technique for producing patterns in thin films formed on substrates. This technique is convenient and advantageous, having regard to the desirability of removing portions of the thin film to be processed without causing damage to the underlying surface. However, a somewhat large number of steps is necessary for completing patterning procedure in accordance with this method. Namely, after forming the thin film to be treated on a substrate, a photoresist film
20 is formed and patterned; the thin film is subjected to an etchant through the patterned photoresist film as a mask and then the photoresist film is removed.

Laser scribing techniques are well known in the art as a low cost patterning method capable of carrying out the scribing at a high speed. YAG laser (IR light, 1.06 microns) is a representative laser which has been generally used for this purpose. Since the optical energy of this laser is
5 only 1.23 eV, however, tin oxide, indium oxide (or ITO), ZnO or so forth having optical energy gaps of about 3 to 4 eV are not effectively processed by the YAG laser. While transparent conductive oxide (CTO) films are generally made of this class.

This laser scribing method has another shortcoming. When portions
10 of a transparent conductive film formed over a soda-lime glass substrate with an ion blocking film therebetween is removed in order to produce electrode patterns thereon, the ion blocking film and the glass substrate are partially eliminated together, and therefore the surface of the glass substrate is exposed. Eventually, in case of liquid crystal device manufacture, the
15 liquid crystal material contained in the device is contaminated by sodium ions introduced from the glass substrate. Furthermore, the scribing makes the upper surface thereof uneven as well as residue remaining on the edges of the removal portions, the residue is piled as high as 0.5 to 1 micron. The unevenness is undesirable not only in regard to the application to
20 liquid crystal devices but also to the manufacture of general electric devices including laminating process. The uneven surface might may be the cause of electrical shorting between different levels of the laminate and disconnection of the electrical patterns superimposed thereon.

SUMMARY OF THE INVENTION

It is an object of the present invention to provide a thin film pattern formed on a glass substrate in order that little contaminant is leaked from the substrate.

5 In accordance with a preferred embodiment, a glass substrate is covered with an alkali ion blocking film made of silicon oxide by sputtering, followed by forming an ITO (indium tin oxide) film. The ITO film is then treated by laser scribing in order to produce a pattern of the ITO film. In this connection, there are several key points for improving
10 the configuration of the pattern as follow.

 The heat transmission is an obstacle to the formation of clear edges of grooves. While laser irradiated portions are heated to its boiling point, the adjacent portions are necessarily heated, reflow and form swollen edges adjacent to the grooves. In order to minimize the formation of the swollen
15 portions which cause disconnection of an overlying film coated thereon, it is necessary to elevate the temperature of the portions to be removed to the boiling point in advance of substantially heating the adjacent portions of the ITO film. This is accomplished by making use of a laser beam having a short wavelength and a short pulse width. The wavelength is selected
20 to be not longer than 400 nm (3.1eV). The pulse length is not longer than 50 nanoseconds. YAG lasers, which have been broadly used in the field, can not emit such a power concentrated laser pulse. The applicant found that eximer lasers could be used for this purpose. In this regards, the damage of the ion blocking film during laser scribing largely depends

on the thermal conductivity thereof. As the thermal conductivity is low, the elevation speed of the ion blocking film becomes low and suffers little influence of heat from the overlying ITO film.

5 The melting points of the ion blocking film and the ITO film are very important. If the ion blocking film is easily molten, there is a chance that openings is formed in the blocking film so that the glass surface is exposed through the grooves. In this regards, the choice of ITO and non-doped SiO_2 is desirable since the melting points of the former and the latter are 890°C and 1700°C respectively. The melting point of the SiO_2 10 film is in turn substantially higher than that of the glass substrate. The energy gaps of them are also suitable for this purpose. SiO has an energy gap of 7 to 8 eV and therefore absorbs little portion of the excimer laser beam of a short wavelength, while ITO has an energy gap of 3 eV.

The method in which only the ITO film is selectively removed by 15 the laser scribing is advantageous having regards to the desirability of smooth and level surface of patterns. Even in accordance with the present invention, residue remains after removal of the ITO film. The residue, however, can be easily eliminated by HCl etch since it is composed of InO_x and SnO_x of porous structure. Unlike this, in accordance with prior 20 art methods utilizing YAG lasers in which the SiO_2 film is eventually partially removed, the residue is formed somewhat integrally with the remaining portions of the ITO and composed of an indium or tin alloy which is mixed with silicon contained in the underlying ion blocking film. The residue can not be eliminated by HCl etch and requires HF etch. 25 Even if HF etch is used, the residue can not be selectively removed independent of the remaining portion of ITO film, which tends to be partially removed together with the overlying ITO film by HF etch.

The ion blocking film is not limited to SiO_2 film formed by sputtering but may be made from other materials as long as the above listed conditions are satisfied. For example, the blocking film can be formed by CVD of SiO_2 or Si_3N_4 films, sputtering of a target of heat resistant glass, such as quartz. Anyway, the formation should be carried out under the softing temperature of the glass substrate.

BRIEF DESCRIPTION OF THE DRAWINGS

Fig. 1 is a schematic diagram showing a laser scribing assembly for laser patterning in accordance with the present invention.

Figs.2(A) to 2(D) are explanatory views showing the shaping process of a laser beam in cross section in accordance with the present invention.

  ~~Figs.3(A) to 3(D) are plan and cross sectional views showing the fabricating process of a thin film pattern in accordance with the present invention.~~

Figs. 4(A) to 4(D) are cross sectional views showing the fabricating process of a glass substrate bearing a thin film pattern suitable for liquid crystal displays in accordance with the present invention.

Figs. 5(A) and 5(B) are microscopic photographs showing the configurations of grooves formed by laser scribing.

Figs. 6(A) and 6(B) are schematic cross sectional views in accordance with the configuration shown in Figs. 5(A) and 5(B).

Figs. 7(A) to 7(D) illustrate a method for manufacturing thin film transistors for an electro-optical device such as an active matrix liquid crystal device.

Fig. 8 illustrates the semiconductor islands covered by the insulating layer as fabricated, for example, by the method step of Fig. 7(B).

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring now to Fig.1, a laser scribing assembly is shown in accordance with the present invention. The laser assembly is comprised of a KrF excimer laser 14 (wavelength = 248nm, $E_g = 5.0$ eV, efficient = 3%, output energy = 350 mJ), a beam expander 15, a mask 16, a convex cylindrical lens 17 made of synthetic quartz and a substrate holder 10. The substrate holder 10 is adapted to slide in the vertical direction as viewed in the illustration in order to change the position of a soda-lime glass substrate 1 mounted thereon. Formed on the substrate 1 are an ion blocking film 2 of 50 to 1500 Å, e.g, 200 Å thickness made of silicon oxide containing very little amount of impurity ions such as phosphorus, sodium and boron ions, and a transparent conductive film of 1000 to 3000 Å thickness made of ITO, tin oxide, zinc oxide or a laminate thereof. The transparent conductive film 4 may be provided with a chromium or molybdenum thin film coating thereon. Depending on the case, an insulating or semiconductor film may be formed under or over the conductive film if necessary.

The height and width of the laser beam after emitted from the excimer laser 14 are 16 mm and 20 mm as illustrated in Fig. 2(A). This laser beam 21 is expanded to have a width of 300 mm as illustrated in Fig. 2(B), while its height remains not changed, by means of the beam expander 15. After expanded, the energy density becomes 5.6×10^{-2} mJ/mm². The expanded beam 22 is then deprived of its periphery by

means of the mask 16 in order to have a height of 2 mm as illustrated in Fig. 2(C). The removal of the peripheral portion of the expanded laser beam is carried out for the purpose of reducing the aberration effect by the subsequent cylindrical lens 17. The flat laser beam 13 is contracted and focussed on the surface of the substrate 1 by means of the lens 17 as illustrated in Fig. 1 and Fig. 2(D). The height of the laser beam at the surface of the substrate 1 is 10 microns. In practice, the grooves to be formed on the substrate may have widths ranging from 2 microns to 200 microns, e.g. 50 microns, 20 microns, 10 microns, 5 microns and 3 microns, depending upon the applications.

The laser beam is repeatedly projected on the substrate 1 in the form of pulses while the substrate is slid relative to the laser beam. The pulse duration is 20 nano seconds and the frequency is 1-100 Hz, for example 10 Hz. Then grooves 35, 36, 37, ... are formed as illustrated in Fig. 3(A) and 3(B). The distance between adjacent ones of the grooves is 15 mm. Residue is left around and inside of the grooves. The residue is selectively removed by an acid, for example, a hydrochloric or hydrofluoric acid (diluted by water at 1/10) or a fluoride solution mixture such as an acidic ammonia fluoride, followed by ultrasonic cleaning (29 KHz) with acetone and pure water.

If the present invention is applied to the manufacture of liquid crystal devices, liquid crystal material, of which high purity is required, is effectively prevented from being contaminated by sodium ions which otherwise would escape from the soda-lime substrate when subjected to long time use. Also, if it is used as the substrate for image sensors, solar cells and the like, amorphous semiconductor films are protected from influence of sodium ions, which tend to result in the degradation of

photoelectric conversion ability and the modification of the semiconductor n-type semiconductor.

5 The ion blocking film is formed by any known techniques such as sputtering, CVD and the like. Preferably, the blocking film is first coated on the substrate in precursor fluid form, e.g. organic silicon liquid compound such as silazanes, alcohol solutions of alcoxysilane, or other
10 suitable liquid compound comprising silicon oxide. A spinner may be used for this coating. Alternatively, screen press printing technique, spraying technique or other coating methods may be used. The precursor film is then heated and transformed into a solid silicon oxide film. Anyway, the use of such a liquid precursor face makes it possible to form a smooth and level surface of the ion blocking film. The thickness of the precursor film is 50-2500 Å.

15 Referring now to Figs. 4(A) to 4(D), a method of manufacturing a glass substrate for liquid crystal displays is described. An ion blocking film 103 made of non-doped silicon oxide is formed on the surface of a soda-lime glass 101. The use of the liquid precursor as explained substrate supra is desirable not only to producing a smooth flat surface but also to dispense with the step of polishing the upper surface of the glass
20 substrate. The thickness of the blocking film is 200 Å.

25 An ITO film 105 is deposited by sputtering to a thickness of 0.1 to 2 microns. As shown in Fig. 1 a train of laser pulses are emitted from an eximer laser and projected on the ITO film 105, while the substrate 101 is slid with the holder 10 in the lateral direction of Fig. 6(B). The pulse projection and the sliding of the substrate 101 are synchronously performed in order that the projections occur at intervals of 390 microns respective to the irradiated ITO film 103. The surface of the ITO film is scanned three

times. Accordingly, the power of the laser pulse is selected to eliminate the ITO film throughout the thickness by three times projection without causing substantial damage to the underlying blocking film 103. Although grooves can be formed only by a single projection of the laser pulse, the use of a plurality of projections is preferred in order to precisely control the effect of the laser scribing and improved the configuration of the pattern. Finally, residue 107 by the sides of the grooves is eliminated by diluted HF etch as illustrated in Fig. 4(D).

Fig. 5(B) is a microscopic photograph of a groove which was formed in a ITO film insulated from a glass substrate by an intervening silicon oxide blocking film in accordance with the present invention. The silicon oxide film was formed with few impurity ions, Fig. 6(B) is a schematic diagram illustrating the cross sectional view of the structure as shown in Fig. 5(B). As seen from the figures, the boundary of the groove was very clear and little residue remained.

Fig. 5(A) is a microscopic photograph of a groove of an ITO film which was formed on a glass substrate with an intervening phosphorus doped SiO_2 film. Fig. 6(A) is a schematic diagram illustrating the cross sectional view of the structure as shown in Fig. 5(A). Since the melting point of the silicon oxide film became low due to the doping of phosphorous ions, the silicon oxide film was molten during the formation of the groove and formed swollen portions by the sides of the groove. The swollen portion was formed with the mixture of silicon oxide and ITO and the elimination thereof was difficult. The glass substrate was exposed through the groove.

From Figs. 5(A), 5(B), 6(A) and 6(B), it is understood that the impurity doping is undesirable and the purity of the silicon oxide is important.

Current leakage was examined by applying a direct voltage of 50 V across each groove. This examination was carried out across 100 grooves and having 30 cm length and 10 microns width. As a result, all the leakage currents were within the range of 1×10^{-9} A to 2×10^{-9} A. This experiment was repeated in case with a phosphorous-doped SiO_2 film in place of the non-doped SiO_2 blocking film. As a result, a little current leakage was observed.

The laser system disclosed in the present invention can be utilized also for annealing semiconductors. A second embodiment of the present invention will be described in conjunction with Figs. 7(A) to 7(D) and Fig. 8. Figs. 7(A) to 7(D) show a method for manufacturing thin film transistors for an electro-optical device such as an active matrix liquid crystal device. In this embodiment, the same laser system used in the first embodiment is employed for crystallizing semiconductor islands.

JS 20 ~~As shown in Fig. 7(A), a non-single crystalline semiconductor film 52 such as an amorphous silicone or solid phase crystallized silicon is formed by plasma CVD on a soda-lime glass substrate 1 having a silicon oxide or silicon nitride blocking layer 51 having a thickness of 1000-4000Å, e.g, 2000Å on its surface. The non-single crystalline semiconductor layer 52 is substantially intrinsic but a suitable dopant species such as boron or arsenic may be added therein. Optionally, hydrogen or a halogen such as fluorine may be added to the semiconductor layer 52 as a dangling bond neutralizer. Also, the semiconductor layer 52 is 200-1500Å thick, for example, 500Å. Further, the semiconductor layer~~

~~is covered by an insulating layer 59 made of silicon oxide or silicon nitride and having a thickness of 200-1500Å.~~

Referring to Fig. 7(B), the semiconductor layer 52 and the insulating layer 59 are simultaneously patterned by a suitable etching method in order to form a plurality of semiconductor islands 58 covered by the insulating layer. The islands are arranged in rows and columns as shown in Fig. 8. For clarification, only 5x5 islands are shown in Fig. 8. However, in practice, 480 x 640 or 960 X 1920 islands may be formed on one substrate. It is also possible to form other semiconductor islands on the same substrate in order to form a driver circuit or peripheral circuit for driving the pixel TFTs.

Subsequently, a laser crystallization in accordance with the present invention is performed to the patterned semiconductor layer. As explained in the first embodiment of the present invention the laser beam finally emitted from the laser system shown in Fig. 1 has a line shape. The width of the line shaped laser beam corresponds to the width of the semiconductor island 58. Alternately, the width of the line shaped laser beam may be slightly larger than the width of the semiconductor island. The energy density of the laser beam is 0.3-0.5 J/cm². The wavelength and the pulse width of the laser beam is, respectively, 248.6 nm or 308 nm and 15 nanoseconds, for example. Thus, a plurality of semiconductor islands arranged in one column line is exposed to the laser beam at one time as shown in Fig. 7(B). The other semiconductor islands arranged in other columns are treated in the same manner by repeating the emission of the laser beam with the substrate moved in one direction as indicated by the arrow 60 in Fig. 7. Actually, either one of the laser optical system or substrate may be moved.

After the crystallization, the insulator 59 is etched off and another insulating layer 53 made of, for example, silicon oxide is formed on the substrate by sputtering at a thickness 500-1500Å, for example 1100Å as shown in Fig. 7(C). The insulating layer 53 will function as a gate insulating layer of each transistor. Further, a doped silicon layer or a metal such as aluminum or tungsten is formed at 2000-6000Å, e.g., 3000Å on the insulating layer 53 and patterned to form a gate electrode 56 on each island. Using the gate electrode 56 as a mask, a dopant species such as boron, phosphorous or arsenic is selectively doped into each semiconductor island 58 using the gate electrode 56 as a mask. Thereby, source and drain regions 57 are formed in each semiconductor island.

Referring to Fig. 7(D), a laser crystallization in accordance with the present invention is again performed in a similar manner as the first laser annealing explained in conjunction with Fig. 7(B). As a result, only the source and drain regions are selectively crystallized by laser annealing. At the same time, the impurity added to the source and drain regions are activated to be p or n-type.

Although omitted from the figure, an interlayer is formed over the gate electrode and contact hole(s) for source, drain and gate electrode is opened, and a second interconnector layer is formed based on the designer's experiment.

As a result, an active matrix circuit for driving a liquid crystal device is produced.

While several embodiments have been specifically described, it is to be appreciated that the present invention is not limited to the particular examples described and that modifications and variations can be made

without departure from the scope of the invention as defined by the append claims. Examples are as follows.

Insulating films constituting a color filter may be integrally formed under or over the transparent conductive film.

5 Although the conductive film is made of a transparent conductive material such as ITO, SiO_2 or ZnO film, a thin film of a metal such as chromium or molybdenum can be used in the same manner.

10 Although in accordance with the preferred embodiment, the grooves are narrow as compared with the remaining transparent conductive film, narrow strips of 20 microns width may be left between removed portion of 400 microns width by making use of a train of pulses which are continuously projected while the substrate is gradually moved.
